(54) Head for string trimmer

(57) A cutting head for a string trimmer is provided which accommodates any string gauge thickness and may be easily and quickly re-threaded upon failure of a string previously disposed therein. Clamping members are provided to clamp the strings within the cutter head, with the clamping force being provided by springs and

centrifugally generated moments. The clamping members are capable of generating two degrees of clamping force. The lesser degree of clamping force can be overcome by a string forcibly inserted into the cutting head.

FIG. 1

EP 0 824 854 A2

Description

BACKGROUND OF THE INVENTION

1. Field of the Invention. This invention is directed to garden string trimmers, and more particularly, to a cutting head for string trimmers which can be easily re-strung.

2. Description of the Prior Art. String trimmers are well known in the prior art. The typical prior art string trimmer comprises a planar cutting head with at least two radially extending strings which is rotated at a sufficient velocity to cause the strings to stiffen. The strings are formed usually from plastic and are sufficiently strong enough to cut through blades of grass, hedges, and other vegetation in a stiffened state. The strings, however, will break upon hitting stone, concrete or some other hard material commonly found in a garden setting.

String trimmers are most often used to cut vegetation along a border of a flower bed or plot of grass which is adjacent to a sidewalk, driveway, or solid structure. Since the cutting head rotates at a speed that makes the strings nearly imperceptible, an operator of the string trimmer is not always able to see that the strings may come into contact with a hard surface and react accordingly. As a result, strings on a string trimmer are commonly broken. Prior art designs of string trimmer cutting heads have attempted to ease the re-stringing process which may be quite time consuming. One type of cutter head design includes an array of grooves and cut-outs in the hub of the cutting head which act to anchor a string therein as in U.S. Patent No. 4,190,954 to Walto entitled "CUTTING HEAD" which issued March 4, 1980, U.S. Patent No. 4,905,465 to Jones, et al. entitled "ROTARY CUTTING MEMBER FOR USE WITH LAWN MOWERS AND THE LIKE" which issued on March 6, 1990, and U.S. Patent No. 5,023,998 to Masciarella, et al. entitled "FILAMENT HOLDER FOR A ROTATING FILAMENT VEGETATION CUTTER" which issued June 18, 1991. This type of cutting head has several drawbacks. First, the grooves and cut-outs include a number of sharp corners which, in time, fray, weaken and break the string disposed therein. Second, a relatively thin string can only be used due to the numerous twists and turns the string must pass through. As a result, the thinner string breaks more often than thicker counter parts and requires repeated replacement. Third, disassembly of the cutter head is required to re-string the cutter head with subsequent bending and manipulation of the string to conform with the grooves and cut-outs formed therein. A typical prior art cutting head requires 1-5 minutes for disassembling and re-stringing. For a commercial gardener who spends eight to ten hours a day using a string trimmer, an hour or more may be wasted for re-stringing.

A second type of string trimmer cutting head design includes a spool of string enclosed within the cutting head, where the string is paid out through peripheral

apertures formed in the circumference of the cutting head as required, as disclosed by U.S. Patent No. 3,708,967 to Geist, et al. entitled "ROTARY CUTTING ASSEMBLY" which issued January 9, 1973, U.S. Patent No. 4,301,642 to Thurber entitled "SAFETY ROTOR FOR MOWER" which issued November 24, 1981, and U.S. Patent No. 4,335,510 to Close, et al. entitled "STRING TRIMMER" which issued June 22, 1982. The string is clamped within the cutting head to prevent unwanted extension therefrom. This cutting head design also has several drawbacks. A failure near an aperture may cause the end of the string to retract within the cutting head, thus requiring disassembly of the cutter head and re-threading of the string through the aperture. Although the cutting head may be designed to be readily removed, the common occurrence of a string failing adds up to a significant amount of time spent in disassembling the cutter head. Also, the operator of the string trimmer must carry the weight of an entire spool during the course of operation, which for a commercial gardener may be a substantial time and even an entire work day, resulting in a strenuous effort.

To overcome some of the shortcomings of the prior art, a third type of string trimmer cutter head design avoids the need for disassembly of the cutter head to accomplish re-stringing. For example, U.S. Patent No. 4,756,146 to Rouse entitled "STRING TRIMMER HEAD AND METHOD" which issued July 12, 1988 includes four arcuate channels, each extending between two points on the periphery of the cutting head. The channels are disposed in pairs so that each pair of channels frictionally engages a string. The string is secured to the cutter head with one end of the string being fed through each channel from a point external to the cutting head and with the ends being pulled through the channels so that the intermediate portion of the string comes into contact with a portion of the periphery of the cutting head disposed between the channels. Another example of the third type of cutting head design is disclosed in U.S. Patent No. 5,398,416 to Mackey entitled "UNIVERSAL STRING TRIMMER REPLACEMENT HEAD" which issued March 21, 1995 and which discloses a cylindrical block formed with two non-parallel channels. A string is secured in the Mackey cutting head through a series of bends with the string passing through the channels and engaging portions of the outer surface of the cutting head. Although these references avoid the requirement of disassembling a cutter head during the re-stringing process, the required number of bends and threading disclosed in these references is also time-consuming. Due to the shortcomings of the prior art, there is a need for a string trimmer cutting head which may be quickly re-strung.

It is an object of this invention to provide a string trimmer cutting head which is easily and quickly re-strung.

It is also an object of this invention to provide a string trimmer cutting head which can be easily and

quickly strung with any gauge string.

It is a further object of this invention to provide a string trimmer cutting head with a centrifugally-driven clamping mechanism for holding the string within the cutting head which allows easy re-stringing of the cutting head.

It is yet another object of this invention to provide a lightweight string trimmer cutting head which contains an amount of string needed only for operation.

It is also another object of this invention to provide a string trimmer cutting head which can be re-strung without disassembly or bending and twisting of the string within the cutting head.

SUMMARY OF THE INVENTION

The above-stated objects are met by a new and improved string trimmer cutting head which can be easily and quickly re-strung and is capable of using thin, as well as thick, gauge string.

The cutting head of the subject invention preferably includes a substantially cylindrical body having a disc-shaped base plate formed to define a central drive shaft aperture and a surrounding side wall. A plurality of slots are formed in the side wall with a radially inward extending pressing wall forming one edge of each of the slots. A clamping member is pivotally mounted adjacent each aperture, opposite the corresponding pressing wall so that its center of gravity is disposed between the pivotal mounting and the corresponding pressing wall. The clamping members are adapted and formed to generate two degrees of clamping force in cooperation with the corresponding pressing walls. Springs are provided to generate one degree of clamping force, wherein the clamping force is sufficient to grippingly engage and maintain strings within the cutting head while not in use. A second and greater degree of clamping force is generated with the cutting head being in use, wherein the rotation of the cutting head creates centrifugal force that acts on the centers of gravity of the clamping members and enhances the gripping force thereof. The lesser degree of clamping force can be overcome by a string forcibly introduced from a location outside the cutting head, through the aperture and between the clamping member and the pressing wall. During operation, the clamping members are rigidly locked into a clamping position from which the greater degree of clamping force is generated. Since string may be threaded through the apertures from a location outside the cutting head, no time-consuming disassembly of the cutting head is required to re-string the cutting head upon failure of a string. An operator of the subject invention may carry a bundle of strings pre-cut to a pre-determined length which can be easily threaded into the cutting head as needed.

In the preferred embodiment, the clamping members are formed with a cam shape, and springs are provided to urge the cam-shaped clamping members into

contact with the corresponding pressing wall. Each cam-shaped clamping member is formed and disposed with its center of gravity being located between the pressing wall and the pivotal mounting. The springs generate the lesser degree of clamping force through the urging of the clamping members into contact with the corresponding pressing walls. During operation, the centrifugal force generated by the rotation of the cutting head acts on the centers of gravity of the clamping members, with resulting torques being generated in the clamping members about the pivotal mountings. Due to the location of the centers of gravity, the torque generated in each clamping member forces the clamping member into greater engagement with the corresponding pressing wall, thereby increasing the clamping force generated by the clamping members and the pressing walls.

The apertures, pressing walls and clamping members are dimensioned to accommodate thin, as well as thick, gauge string. Thus, the new and improved cutting head of the subject invention is capable of accommodating relatively strong strings which reduce likelihood of failure. The accommodation of thicker strings, which reduces the number of failures, and the ease of re-threading reduce an operator's lost time spent on re-stringing a string trimmer.

These and other features of the invention will be better understood through a study of the following detailed description of the invention and the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a perspective view of the new and improved cutting head of the subject invention.

FIG. 2 is a plan view of the new and improved cutting head of the subject invention.

FIG. 3 is a partial view of a string clamped by the new and improved cutting head of the subject invention.

FIG. 4 is a partial view of a second embodiment of the new and improved cutting head of the subject invention.

FIG. 5 is a partial view of a third embodiment of the new and improved cutting head of the subject invention.

FIG. 6 is a partial view of a fourth embodiment of the new and improved cutting head of the subject invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring to FIG. 1, the cutter head 10 is rotationally driven by a motor, not shown, through a drive shaft 12 which spins strings 14 at a velocity sufficient to cut vegetation. Unkept vegetation, such as a tuft of grass 16, may be cut to a desired height as shown by tuft 18 and blade of grass 20.

FIG. 2 more clearly shows the preferred embodi-

ment of the cutting head 10 which includes a disc-shaped base plate 22 formed with a central hub 24. The base plate 22 is preferably formed with a circular shape. Alternatively, the base plate 22 can be formed with any shape that allows the base plate 22 to rotate about its center in a balanced state. For example, the base plate 22 can be formed as a rectangle or a star with equally-spaced points. Also, the cutting head 10 can be formed to various sizes by cutting the base plate 22 to the desired dimensions.

The hub 24 is frustoconically shaped and extends from the base plate 22 in a single direction. A drive shaft aperture 26 is formed in the hub 24 and dimensioned to allow a drive shaft to pass therethrough. The drive shaft may be secured to the hub 24 in the void formed by the hub 24 above the plane of the base plate 22. A side wall 28 also extends from the base plate 22 in the same direction as the hub 24 to a height equal to or greater than the height of the hub 24. The side wall 28 is discontinuous with edges 30 and pressing walls 32 forming the ends of each length of the side wall 28.

The edges 30 and the pressing walls 32 both extend radially inward towards the hub 24 with the pressing walls 32 having a height equal to that of the side wall 28. The edges 30 are formed with a height, as measured from the base plate 22, considerably less than the side wall 28. The edges 30 and the pressing walls 32 are disposed to define apertures 34 at opposing locations in the side wall 28. The apertures 34 are each formed with a width capable of accommodating the string 14 embodying any commonly used thickness. The side wall 28 may be formed with any number of the apertures 34, so long the apertures 34 are disposed at equal intervals along the length of the side wall 28. The equal spacing of the apertures 34 is required to maintain the cutting head 10 balanced as the cutting head 10 rotates during use. As shown in FIG. 1, a cover 35 is provided which is formed to engage the side wall 28 opposite the base plate 22 and prevent the introduction of dirt and debris into the cutting head 10. The cover 35 is formed to allow a drive shaft to pass therethrough.

Referring to FIG. 2, cams 36 are pivotally mounted to post 38 which extend from the edges 30. The cams 36 are mounted so that the top surface of the cams is below the height of the pressing walls 32. Springs 40 are provided to bias the cams 36, with each of the springs 40 having one end secured to one of the cams 36 and a second end secured to a bracket 42 formed in the side wall 28. The cams 36 are formed and mounted onto the posts 38 so that the center of gravity of each of the cams 36 is located at a point between the corresponding post 38 and the pressing wall 32, as shown in FIG. 3 with the center of gravity indicated by "C. G.". The springs 40 are secured to the cams 36 such that the cams 36 are urged in a clockwise direction into contact with the pressing wall 32, as shown in FIG. 2. The springs 40 create the lesser degree of clamping force which is capable of maintaining the string 14 between

the cam 36 in the pressing wall 32. The spring force of the spring 40 is selected to allow counter-clockwise rotation of the cams 36 with the insertion of the strings 14 into the cutting head 10 from a location outside the side wall 28. The rotation of the cutting head 10 during use, in either a clockwise or counter-clockwise direction, creates a centrifugal force which acts on the centers of gravity of the cams 36 and creates torque about the posts 38 which cause the cams 36 to come into tighter engagement with the strings 14. Also, the centrifugal force radially extends the strings 14 and causes a thinning effect with the cross-section of the strings 14 being slightly reduced, thereby allowing the springs 40 and the torque acting on the cams 36 to urge the cams 36 into closer engagement with the pressing walls 32 and create an even tighter engagement of the cams 36 and the pressing walls 32 about the strings 14.

In operation, the cutting head 10 is mounted onto a rotational drive shaft which passes through the cover 35 and the drive shaft aperture 26 with the drive shaft being secured to the hub 24. One end of the string 14 is guided through one of the apertures 34 formed in the side wall 28 and forced between the cam 36 and the pressing wall 32. The passage of the string 14 between the cam 36 and the pressing wall 32 causes the cam to rotate in a counter-clockwise direction. Once the string 14 is forced into the cutting head 10, no further force is required and the spring 40 urges the cam 36 into clockwise rotation, resulting in the string 14 being clamped between the cam 36 and the pressing wall 32. The string 14 cannot be easily pulled out of the cutting head 10 since a force acting on the string 14 in a radially outward direction will also act on the cam 36 to cause it to rotate further clockwise and create a greater clamping force.

With the cutting head 10 rotating in either direction, the clamping force is enhanced due to centrifugal force created by the rotation of the cutting head 10 acting on the centers of gravity of the cams 36, which in turn, create torque about the post 38 and cause the cams 36 to come into tighter engagement with the strings 14. If one of the strings 14 fails during use, an operator of the cutting head 10 merely has to force a new string into the cutting head 10. The subject invention does not require disassembly of the cutting head 10 to accomplish rethreading. The ends of the broken string are merely forced into the cutting head 10 without affecting the operation of the cutting head 10. Periodically, the cutting head 10 may be opened to dispose of the fragments of broken string.

In a second embodiment, torsional springs 44 may be employed about the posts 38 as shown in FIG. 4 in place of the coil springs 40. One end 46 of the torsional spring 44 is secured to the edge 30 with the other end 48 being secured to the cam 36 as shown in the cut-away section of FIG. 4. The end 48 urges the cam 36 in a clockwise direction about the post 38, with the operation of the second embodiment of the subject invention

being similar to that described above.

Alternatively, the cam 36 can be substituted for a different-shaped clamping member. As shown in FIG. 5, a cylindrical rod 50 may be pivotally mounted to the post 38 with its center of gravity located between the post 38 and the pressing wall 32. Any shaped clamping member may be used with the subject invention so long as it is formed with its center of gravity disposed between the post 38 and the pressing wall 32 and comprises an edge or face which can cooperate with the pressing wall 32 to clamp the string 14.

In a fourth embodiment, the cutting head 10 may be formed with the cams 36 capable of frictionally engaging the strings 14 without the use of springs 40. As shown in FIG. 6, the post 38 may extend through the edge 30, or through the cover 35, not shown. A handle 52 is provided at the end of the post 38 opposite the cams 36. The cam 36 may be manually rotated about the post 38 by rotating the handle 52. The cam 36 forms an opening with the pressing wall having a width "D" which may be varied. The width "D" is measured between the closest points of the cam 36 and the pressing wall 32 and represents the narrowest cross-section of the opening. The string 14 is formed with a diameter "d". To dispose the string 14 within the cutting head 10, the cam 36 is rotated so that the width "D" of the opening is greater than the diameter "d" of the string 14. Once within the cutting head 10, the cam 36 is rotated to frictionally engage the string 14 and press the string 14 against the pressing wall 32, with the width "D" being less than the diameter "d" of the string 14. A plurality of spaced ribs 54 may be provided to enhance the frictional engagement of the cam 36 with the string 14. In use, the centrifugal force created by the rotation of the cutting head 10 acts on the center of gravity of the cam 36, indicated by "C.G.", to enhance the gripping engagement of the string 14. The rotation of the cutting head 10 causes the cam 36 to create a moment about the post 38 and clamp string 14 in tighter engagement. Also, the cams 36 can be substituted for different-shaped clamping member which is formed with a center of gravity disposed between the post 38 and the pressing wall 32 during use and comprise an edge or face which can frictionally engage the string 14.

As is readily apparent, numerous modifications and changes may readily occur to those skilled in the art, and hence it is not desired to limit the invention to the exact construction and operation shown and described, and accordingly all suitable modification equivalents may be resorted to falling within the scope of the invention as claimed.

Claims

1. A combination of a cutting head and string for cutting and trimming vegetation, said combination being selectively rotationally driven through a drive shaft, said combination comprising:

at least one generally straight length of string, each said string having two ends and an intermediate portion extending therebetween;

a head selectively rotationally driven by the drive shaft, said head having a base plate and a side wall, said base plate defining a periphery, said side wall extending from said periphery, said base plate and said side wall collectively defining a volume, said side wall being formed with at least one aperture corresponding to each said string, wherein each said string is disposed to extend through a single said aperture such that one said end of each said string is disposed in said volume defined by said base plate and said side wall, wherein a segment of said intermediate portion of each said string is disposed in said volume, each said segment being substantially unbent; and

at least one clamping means for selectively fixing each said string to said head.

2. A cutting head as in claim 1, wherein each said clamping means includes a pivotally mounted clamping member and a pressing wall aligned to cooperatively clamp the string.
3. A cutting head as in claim 2, wherein each said clamping member being formed with a center of gravity disposed between respective said pivotal mounting and cooperating said pressing wall.
4. A cutting head as in any of the preceding claims, wherein the fixing force generated by each said clamping means is at least partially generated by a biasing means, such as a coil spring or a torsional spring.
5. A cutting head as in claim 4, wherein each said clamping member has a contact surface for engagement with the string, and wherein each said biasing means is adapted to urge said contact surface of respective said clamping member generally towards said aperture which is adjacent respective said clamping member.
6. A cutting head as in claims 1 and 2, wherein said clamping means is manually actuatable, said manually actuatable clamping means having at least two positions including a manually actuated locked clamping position wherein the string is clamped by said clamping means and a manually actuated unlocked clamping position wherein the string is not clamped by said clamping means.
7. A cutting head as in claim 6, wherein said clamping member is formed with a handle to allow manual actuation thereof between said locked clamping

position and said unlocked clamping position.

8. A cutting head as in any of the preceding claims,
wherein each said pressing wall is formed continu-
ously with a portion of said side wall. 5
9. A cutting head as in any of the preceding claims,
wherein said clamping member having the shape
selected from a group consisting of a cam shape or
a cylindrical rod shape. 10
10. A cutting head as in any of the preceding claims,
wherein each said clamping member is formed with
a plurality of spaced ribs for enhancing frictional
engagement with the string. 15
